

The Backpack algorithm

May 11, 2015

This document describes the Backpack shaping and typechecking passes, as we intend to implement it.

1 Changelog

April 28, 2015 A signature declaration no longer provides a signature in the technical shaping sense; the motivation for this change is explained in **In-scope signatures are not provisions**. The simplest consequence of this is that all requirements are importable (Derek has stated that he doesn't think this will be too much of a problem in practice); it is also possible to extend shape with a **signatures** field, although some work has to be done specifying coherence conditions between **signatures** and **requirements**.

2 Front-end syntax

p, q, r	Package names	
m, n	Module names	
Packages		
pkg	$::=$	<code>package p [$provreq$] where $\{d_1; \dots; d_n\}$</code>
Declarations		
d	$::=$	<code>module m [$exports$] where $body$</code> <code> signature m [$exports$] where $body$</code> <code> include p [$provreq$]</code>
Provides/requires specification		
$provreq$	$::=$	<code>(rns) [requires(rns)]</code>
rns	$::=$	<code>$rn_0, \dots, rn_n[,]$</code> Renamings
rn	$::=$	<code>m as n</code> Renaming
Haskell code		
$exports$		A Haskell module export list
$body$		A Haskell module body

Figure 1: Syntax of Backpack

The syntax of Backpack is given in Figure 1. See the “Backpack manual” for more explanation about the syntax. It is slightly simplified here by removing any constructs which are easily implemented as syntactic sugar (e.g., a bare m in a renaming is simply m as m .)

3 Shaping

```
Shape ::= provides: m -> Module { Name, ... }; ...  
        requires: m -> { Name, ... }; ...  
PkgKey ::= p(m -> Module, ... )  
Module ::= PkgKey:m  
Name ::= Module.OccName  
OccName Unqualified name in a namespace
```

Figure 2: Semantic entities in Backpack

Shaping computes a *Shape*, whose form is described in Figure 2. Initializing the shape context to the empty shape, we incrementally build the context as follows:

1. Calculate the shape of a declaration, with respect to the current shape context. (e.g., by renaming a module/signature, or using the shape from an included package.)
2. Merge this shape into the shape context.

The final shape context is the shape of the package as a whole. Optionally, we can also compute the renamed syntax trees of modules and signatures.

In the description below, we'll assume **THIS** is the package key of the package being processed.

3.1 module M

A module declaration provides a module **THIS:M** at module name **M**. It has the shape:

```
provides: M -> THIS:M { exports of renamed M }  
requires: (nothing)
```

Example:

```
module A(T) where  
  data T = T  
  
-- provides: A -> THIS:A { THIS:A.T }  
-- requires: (nothing)
```

OccName is implied by **Name**. In Haskell, the following is not valid syntax:

```
import A (foobar as baz)
```

In particular, a **Name** which is in scope will always have the same **OccName** (even if it may be qualified.) You might imagine relaxing this restriction so that declarations can be used under different **OccNames**; in such a world, we need a different definition of shape:

```
Shape ::=  
  provided: ModName -> { OccName -> Name }  
  required: ModName -> { OccName -> Name }
```

Presently, however, such an **OccName** annotation would be redundant: it can be inferred from the **Name**.

Holes of a package are a mapping, not a set. Why can't the `PkgKey` just record a set of `Modules`, e.g. `PkgKey ::= SrcPkgKey { Module }`? Consider:

```
package p (A) requires (H1, H2) where
  signature H1(T) where
    data T
  signature H2(T) where
    data T
  module A(A(..)) where
    import qualified H1
    import qualified H2
    data A = A H1.T H2.T

package q (A12, A21) where
  module I1(T) where
    data T = T Int
  module I2(T) where
    data T = T Bool
  include p (A as A12) requires (H1 as I1, H2 as I2)
  include p (A as A21) requires (H1 as I2, H2 as I1)
```

With a mapping, the first instance of `p` has key `p(H1 -> q():I1, H2 -> q():I2)` while the second instance has key `p(H1 -> q():I2, H2 -> q():I1)`; with a set, both would have the key `p(q():I1, q():I2)`.

Signatures can require a specific entity. With requirements like `A -> { HOLE:A.T, HOLE:A.foo }`, why not specify it as `A -> { T, foo }`, e.g., `required: { ModName -> { OccName } }`? Consider:

```
package p () requires (A, B) where
  signature A(T) where
    data T
  signature B(T) where
    import T
```

The requirements of this package specify that `A.T = B.T`; this can be expressed with `Names` as

```
A -> { HOLE:A.T }
B -> { HOLE:A.T }
```

But, without `Names`, the sharing constraint is impossible: `A -> { T }`; `B -> { T }`. (NB: `A` and `B` don't have to be implemented with the same module.)

The Name of a value is used to avoid ambiguous identifier errors. We state that two types are equal when their **Names** are the same; however, for values, it is less clear why we care. But consider this example:

```
package p (A) requires (H1, H2) where
  signature H1(x) where
    x :: Int
  signature H2(x) where
    import H1(x)
  module A(y) where
    import H1
    import H2
    y = x
```

The reference to **x** in **A** is unambiguous, because it is known that **x** from **H1** and **x** from **H2** are the same (have the same **Name**.) If they were not the same, it would be ambiguous and should cause an error. Knowing the **Name** of a value distinguishes between these two cases.

Absence of Module in requires implies holes are linear Because the requirements do not record a **Module** representing the identity of a requirement, it means that it's not possible to assert that hole **A** and hole **B** should be implemented with the same module, as might occur with aliasing:

```
signature A where
signature B where
alias A = B
```

The benefit of this restriction is that when a requirement is filled, it is obvious that this is the only requirement that is filled: you won't magically cause some other requirements to be filled. The downside is it's not possible to write a package which looks for an interface it is looking for in one of *n* names, accepting any name as an acceptable linkage. If aliasing was allowed, we'd need a separate physical shaping context, to make sure multiple mentions of the same hole were consistent.

3.2 signature M

A signature declaration creates a requirement at module name **M**. It has the shape:

```
provides: (nothing)
requires: M -> { exports of renamed M }
```

Example:

```
signature H(T) where
  data T

-- provides: H -> (nothing)
-- requires: H -> { HOLE:H.T }
```

In-scope signatures are not provisions. We enforce the invariant that a provision is always (syntactically) a **module** and a requirement is always a **signature**. This means that if you have a requirement and a provision of the same name, the requirement can *always* be filled with the provision. Without this invariant, it's not clear if a provision will actually fill a signature. Consider this example, where a signature is required and exposed:

```
package a-sigs (A) requires (A) where -- ***
  signature A where
    data T

package a-user (B) requires (A) where
  signature A where
    data T
    x :: T
  module B where
    ...

package p where
  include a-sigs
  include a-user
```

When we consider merging in the shape of **a-user**, does the **A** provided by **a-sigs** fill in the **A** requirement in **a-user**? It *should not*, since **a-sigs** does not actually provide enough declarations to satisfy **a-user**'s requirement: the intended semantics *merges* the requirements of **a-sigs** and **a-user**.

```
package a-sigs (M as A) requires (H as A) where
  signature H(T) where
    data T
  module M(T) where
    import H(T)
```

We rightly should error, since the provision is a module. And in this situation:

```
package a-sigs (H as A) requires (H) where
  signature H(T) where
    data T
```

The requirements should be merged, but should the merged requirement be under the name **H** or **A**? It may still be possible to use the **(A) requires (A)** syntax to indicate exposed signatures, but this would be a mere syntactic alternative to **() requires (exposed A)**.

3.3 include pkg (X) requires (Y)

We merge with the transformed shape of package `pkg`, where this shape is transformed by:

- Renaming and thinning the provisions according to (X)
- Renaming requirements according to (Y) (requirements cannot be thinned, so non-mentioned requirements are implicitly passed through.) For each renamed requirement from `Y` to `Y'`, substitute `HOLE:Y` with `HOLE:Y'` in the `Modules` and `Names` of the `provides` and `requires`.

If there are no thinnings/renamings, you just merge the shape unchanged! Here is an example:

```
package p (M) requires (H) where
  signature H where
    data T
  module M where
    import H
    data S = S T

package q (A) where
  module X where
    data T = T
  include p (M as A) requires (H as X)
```

The shape of package `p` is:

```
requires: M -> { p(H -> HOLE:H):M.S }
provides: H -> { HOLE:H.T }
```

Thus, when we process the `include` in package `q`, we make the following two changes: we rename the provisions, and we rename the requirements, substituting `HOLEs`. The resulting shape to be merged in is:

```
provides: A -> { p(H -> HOLE:X):M.S }
requires: X -> { HOLE:X.T }
```

After merging this in, the final shape of `q` is:

```
provides: X -> { q():X.T }           -- from shaping 'module X'
          A -> { p(H -> q():X):M.S }
requires: (nothing)                  -- discharged by provided X
```

3.4 Merging

The shapes we’ve given for individual declarations have been quite simple. Merging combines two shapes, filling requirements with implementations, unifying **Names**, and unioning requirements; it is the most complicated part of the shaping process.

The best way to think about merging is that we take two packages with inputs (requirements) and outputs (provisions) and “wiring” them up so that outputs feed into inputs. In the absence of mutual recursion, this wiring process is *directed*: the provisions of the first package feed into the requirements of the second package, but never vice versa. (With mutual recursion, things can go in the opposite direction as well.)

Suppose we are merging shape p with shape q (e.g., $p; q$). Merging proceeds as follows:

1. *Fill every requirement of q with provided modules from p .* For each requirement M of q that is provided by p (in particular, all of its required **Names** are provided), substitute each **Module** occurrence of **HOLE:M** with the provided $p(M)$, unify the names, and remove the requirement from q . If the names of the provision are not a superset of the required names, error.
2. If mutual recursion is supported, *fill every requirement of p with provided modules from q .*
3. *Merge leftover requirements.* For each requirement M of q that is not provided by p but required by p , unify the names, and union them together to form the new requirement. (It’s not necessary to substitute **Modules**, since they are guaranteed to be the same.)
4. *Add provisions of q .* Union the provisions of p and q , erroring if there is a duplicate that doesn’t have the same identity.

To unify two sets of names, find each pair of names with matching **OccNames** n and m and do the following:

1. If both are from holes, pick a canonical representative m and substitute n with m .
2. If one n is from a hole, substitute n with m .
3. Otherwise, error if the names are not the same.

It is important to note that substitutions on **Modules** and substitutions on **Names** are disjoint: a substitution from **HOLE:A** to **HOLE:B** does *not* substitute inside the name **HOLE:A.T**.

Since merging is the most complicated step of shaping, here are a big pile of examples of it in action.

3.4.1 A simple example

In the following set of packages:

```
package p(M) requires (A) where
  signature A(T) where
    data T
  module M(T, S) where
    import A(T)
    data S = S T

package q where
  module A where
    data T = T
  include p
```

When we **include** p , we need to merge the partial shape of q (with just provides A) with the shape of p . Here is each step of the merging process:

shape 1	shape 2
<hr style="border-top: 1px dashed black;"/>	
(initial shapes)	
provides: A -> THIS:A { q():A.T }	M -> p(A -> HOLE:A) { HOLE:A.T, p(A -> HOLE:A).S }
requires: (nothing)	A -> { HOLE:A.T }
(after filling requirements)	
provides: A -> THIS:A { q():A.T }	M -> p(A -> THIS:A) { q():A.T, p(A -> THIS:A).S }
requires: (nothing)	(nothing)
(after adding provides)	
provides: A -> THIS:A { q():A.T }	
	M -> p(A -> THIS:A) { q():A.T, p(A -> THIS:A).S }
requires: (nothing)	

Notice that we substituted HOLE:A with THIS:A, but HOLE:A.T with q():A.T.

3.4.2 Requirements merging can affect provisions

When a merge results in a substitution, we substitute over both requirements and provisions:

```
signature H(T) where
  data T
module A(T) where
  import H(T)
module B(T) where
  data T = T

-- provides: A -> THIS:A { HOLE:H.T }
--           B -> THIS:B { THIS:B.T }
-- requires: H -> { HOLE:H.T }

signature H(T, f) where
  import B(T)
  f :: a -> a

-- provides: A -> THIS:A { THIS:B.T }           -- UPDATED
--           B -> THIS:B { THIS:B.T }
-- requires: H -> { THIS:B.T, HOLE:H.f } -- UPDATED
```

3.4.3 Sharing constraints

Suppose you have two signature which both independently define a type, and you would like to assert that these two types are the same. In the ML world, such a constraint is known as a sharing constraint. Sharing constraints can be encoded in Backpacks via clever use of reexports; they are also an instructive example for signature merging.

```
signature A(T) where
  data T
signature B(T) where
  data T

-- requires: A -> { HOLE:A.T }
```

```

        B -> { HOLE:B.T }

-- the sharing constraint!
signature A(T) where
    import B(T)
-- (shape to merge)
-- requires: A -> { HOLE:B.T }

-- (after merge)
-- requires: A -> { HOLE:A.T }
--           B -> { HOLE:A.T }

```

I'm pretty sure any choice of **Name** is OK, since the subsequent substitution will make it alpha-equivalent.

3.5 Export declarations

If an explicit export declaration is given, the final shape is the computed shape, minus any provisions not mentioned in the list, with the appropriate renaming applied to provisions and requirements. (Requirements are implicitly passed through if they are not named.) If no explicit export declaration is given, the final shape is the computed shape, including only provisions which were defined in the declarations of the package.

3.6 Package key

What is **THIS**? It is the package name, plus for every requirement *M*, a mapping *M* -> *HOLE:M*. Annoyingly, you don't know the full set of requirements until the end of shaping, so you don't know the package key ahead of time; however, it can be substituted at the end easily.

Signature visibility, and defaulting The simplest formulation of requirements is to have them always be visible. Signature visibility could be controlled by associating every requirement with a flag indicating if it is importable or not: a signature declaration sets a requirement to be visible, and an explicit export list can specify if a requirement is to be visible or not.

When an export list is absent, we have to pick a default visibility for a signature. If we use the same behavior as with modules, a strange situation can occur:

```
package p where -- S is visible
  signature S where
    x :: True

package q where -- use defaulting
  include p
  signature S where
    y :: True
  module M where
    import S
    z = x && y      -- OK

package r where
  include q
  module N where
    import S
    z = y          -- OK
    z = x          -- ???
```

Absent the second signature declaration in `q`, `S.x` clearly should not be visible in `N`. However, what ought to occur when this signature declaration is added? One interpretation is to say that only some (but not all) declarations are provided (`S.x` remains invisible); another interpretation is that adding `S` is enough to treat the signature as “in-line”, and all declarations are now provided (`S.x` is visible).

The latter interpretation avoids having to keep track of providedness per declarations, and means that you can always express defaulting behavior by writing an explicit provides declaration on the package. However, it has the odd behavior of making empty signatures semantically meaningful:

```
package q where
  include p
  signature S where
```

4 Type constructor exports

In the previous section, we described the `Names` of a module as a flat namespace; but actually, there is one level of hierarchy associated with type-constructors. The type:

```
data A = B { foo :: Int }
```

brings three `OccNames` into scope, `A`, `B` and `foo`, but the constructors and record selectors are considered *children* of `A`: in an import list, they can be implicitly brought into scope with `A(..)`, or individually brought into scope with `foo` or `pattern B` (using the new `PatternSynonyms` extension). Symmetrically, a module may export only *some* of the constructors/selectors of a type; it may not even export the type itself!

We *absolutely* need this information to rename a module or signature, which means that there is a little bit of extra information we have to collect when shaping. What is this information? If we take GHC's internal representation at face value, we have the more complex semantic representation seen in Figure 3:

<i>Shape</i>	<code>::= provides: m -> Module { AvailInfo, ... }; ...</code> <code>requires: m -> { AvailInfo, ... }; ...</code>	
<i>AvailInfo</i>	<code>::= Name</code> <code> Name { Name₀, ..., Name_n }</code>	Plain identifiers Type constructors

Figure 3: Enriched semantic entities in Backpack

For type constructors, the outer *Name* identifies the *parent* identifier, which may not necessarily be in scope (define this to be the `availName`); the inner list consists of the children identifiers that are actually in scope. If a wildcard is written, all of the child identifiers are brought into scope. In the following examples, we've ensured that types and constructors are unambiguous, although in Haskell proper they live in separate namespaces; we've also elided the `THIS` package key from the identifiers.

```
module M(A(..)) where
  data A = B { foo :: Int }
  -- M.A{ M.A, M.B, M.foo }

module N(A) where
  data A = B { foo :: Int }
  -- N.A{ N.A }

module O(foo) where
  data A = B { foo :: Int }
  -- O.A{ O.foo }

module A where
  data T = S { bar :: Int }
module B where
  data T = S { baz :: Bool }
module C(bar, baz) where
  import A
  import B
  -- A.T{ A.bar }, B.T{ B.baz }
  -- NB: it would be illegal for the type constructors
  -- A.T and B.T to be both exported from C!
```

Previously, we stated that we simply merged *Names* based on their *OccNames*. We now must consider what it means to merge *AvailInfos*.

4.1 Algorithm

Our merging algorithm takes two sets of *AvailInfos* and merges them into one set. In the degenerate case where every *AvailInfo* is a *Name*, this algorithm operates the same as the original algorithm. Merging proceeds in two steps: unification and then simple union.

Unification proceeds as follows: for each pair of *Names* with matching *OccNames*, unify the names. For each pair of *Name* $\{Name_0, \dots, Name_n\}$, where there exists some pair of child names with matching *OccNames*, unify the parent *Names*. (A single *AvailInfo* may participate in multiple such pairs.) A simple identifier and a type constructor *AvailInfo* with overlapping in-scope names fails to unify. After unification, the simple union combines entries with matching *availNames* (parent name in the case of a type constructor), recursively unioning the child names of type constructor *AvailInfos*.

Unification of *Names* results in a substitution, and a *Name* substitution on *AvailInfo* is a little unconventional. Specifically, substitution on *Name* $\{Name_0, \dots, Name_n\}$ proceeds specially: a substitution from *Name* to *Name'* induces a substitution from *Module* to *Module'* (as the *OccNames* of the *Names* are guaranteed to be equal), so for each child *Name_i*, perform the *Module* substitution. So for example, the substitution *HOLE:A.T* to *THIS:A.T* takes the *AvailInfo* *HOLE:A.T* $\{HOLE:A.B, HOLE:A.foo\}$ to *THIS:A.T* $\{THIS:A.B, THIS:A.foo\}$. In particular, substitution on children *Names* is *only* carried out by substituting on the outer name; we will never directly substitute children.

4.2 Examples

Unfortunately, there are a number of tricky scenarios:

Merging when type constructors are not in scope

```
signature A1(foo) where
  data A = A { foo :: Int, bar :: Bool }

signature A2(bar) where
  data A = A { foo :: Int, bar :: Bool }
```

If we merge *A1* and *A2*, are we supposed to conclude that the types *A1.A* and *A2.A* (not in scope!) are the same? The answer is no! Consider these implementations:

```
module A1(A(..)) where
  data A = A { foo :: Int, bar :: Bool }

module A2(A(..)) where
  data A = A { foo :: Int, bar :: Bool }

module A(foo, bar) where
  import A1
  import A2
```

Here, module *A1* implements *signature A1*, module *A2* implements *signature A2*, and module *A* implements *signature A1* and *signature A2* individually and should certainly implement their merge. This is why we cannot simply merge type constructors based on the *OccName* of their top-level type; merging only occurs between in-scope identifiers.

Does merging a selector merge the type constructor?

```
signature A1(A(..)) where
  data A = A { foo :: Int, bar :: Bool }
```

```
signature A2(A(..)) where
  data A = A { foo :: Int, bar :: Bool }

signature A2(foo) where
  import A1(foo)
```

Does the last signature, which is written in the style of a sharing constraint on `foo`, also cause `bar` and the type and constructor `A` to be unified? Because a merge of a child name results in a substitution on the parent name, the answer is yes.

Incomplete data declarations

```
signature A1(A(foo)) where
  data A = A { foo :: Int }

signature A2(A(bar)) where
  data A = A { bar :: Bool }
```

Should `A1` and `A2` merge? If yes, this would imply that data definitions in signatures could only be *partial* specifications of their true data types. This seems complicated, which suggests this should not be supported; however, in fact, this sort of definition, while disallowed during type checking, should be *allowed* during shaping. The reason that the shape we ascribe to the signatures `A1` and `A2` are equivalent to the shapes for these which should merge:

```
signature A1(A(foo)) where
  data A = A { foo :: Int, bar :: Bool }

signature A2(A(bar)) where
  data A = A { foo :: Int, bar :: Bool }
```

4.3 Subtyping record selectors as functions

```
signature H(foo) where
  data A
  foo :: A -> Int

module M(foo) where
  data A = A { foo :: Int, bar :: Bool }
```

Does `M` successfully fill `H`? If so, it means that anywhere a signature requests a function `foo`, we can instead validly provide a record selector. This capability seems quite attractive but actually it is quite complicated, because we can no longer assume that every child name is associated with a parent name.

As a workaround, `H` can equivalently be written as:

```
signature H(foo) where
  data A = A { foo :: Int, bar :: Bool }
```

This is suboptimal, however, as the otherwise irrelevant `bar` must be mentioned in the definition.

So what if we actually want to write the original signature `H`? The technical difficulty is that we now need to unify a plain identifier *AvailInfo* (from the signature) with a type constructor *AvailInfo* (from a module.) It is not clear what this should mean. Consider this situation:

```
package p where
```

```

signature H(A, foo, bar) where
  data A
  foo :: A -> Int
  bar :: A -> Bool
module X(A, foo) where
  import H
package q where
  include p
  signature H(bar) where
    data A = A { foo :: Int, bar :: Bool }
  module Y where
    import X(A(..)) -- ???

```

Should the wildcard import on X be allowed? Probably not? How about this situation:

```

package p where
  -- define without record selectors
  signature X1(A, foo) where
    data A
    foo :: A -> Int
  module M1(A, foo) where
    import X1

package q where
  -- define with record selectors (X1s unify)
  signature X1(A(..)) where
    data A = A { foo :: Int, bar :: Bool }
  signature X2(A(..)) where
    data A = A { foo :: Int, bar :: Bool }

  -- export some record selectors
  signature Y1(bar) where
    import X1
  signature Y2(bar) where
    import X2

package r where
  include p
  include q

  -- sharing constraint
  signature Y2(bar) where
    import Y1(bar)

  -- the payload
  module Test where
    import M1(foo)
    import X2(foo)
    ... foo ... -- conflict?

```

Without the sharing constraint, the foos from M1 and X2 should conflict. With it, however, we should conclude that the foos are the same, even though the foo from M1 is *not* considered a child of A, and even though in the sharing constraint we *only* unified bar (and its parent A). To know that foo from M1 should also

be unified, we have to know a bit more about **A** when the sharing constraint performs unification; however, the *AvailInfo* will only tell us about what is in-scope, which is *not* enough information.

5 Type checking

```

PkgType ::= ModIface0; ...; ModIfacen

Module interface
ModIface ::= module Module (mi_exports) where
                mi_decls
                mi_insts
mi_exports ::= AvailInfo0, ... , AvailInfon
mi_decls   ::= IfaceDecl0; ...; IfaceDecln
mi_insts   ::= IfaceClsInst0; ...; IfaceClsInstn

Interface declarations
IfaceDecl ::= OccName :: IfaceId
                | data OccName = IfaceData
                | ...
IfaceClsInst A type-class instance
IfaceId      Interface of top-level binder
IfaceData    Interface of type constructor

```

Figure 4: Module interfaces in GHC

Type checking an indefinite package (a package with holes) involves calculating, for every module, a *ModIface* representing the type/interface of the module in question (which is serialized to disk). The general form of these interface files are described in Figure 4; notably, the interfaces *IfaceId*, *IfaceData*, etc. contain *Name* references, which must be resolved by looking up a *ModIface* corresponding to the *Module* associated with the *Name*. (We will say more about this lookup process shortly.) For example, given:

```

package p where
  signature H where
    data T
  module A(S, T) where
    import H
    data S = S T

```

the *PkgType* is:

```

module HOLE:H (HOLE:H.T) where
  data T -- abstract type constructor
module THIS:A (THIS:A.S, HOLE:H.T) where
  data S = S HOLE:H.T
-- where THIS = p(H -> HOLE:H)

```

However, a *PkgType* of *ModIfaces* is not the whole story: when a package has holes, a *PkgType* specified in this manner defines a family of possible types, based on how the holes are shaped and instantiated. A package which writes `include p requires (H as S)` and has a sharing constraint of `H.T` with `q():B.T` may end up with this “type”:

```

module HOLE:S (q():B.T) where

```

```

module THIS:A (THIS:A.S, q():B.T) where
  data S = S q():B.T
  -- where THIS = p(H -> HOLE:S)

```

Furthermore, for ease of implementation, GHC prefers to resolve all indirect *Name* references (which are just strings) into a *ModIface* into direct *TyThing* references (which are data structures that have type information). This resolution is done lazily with some hackery!

Thus, given a shaping and a hole instantiation, a *ModIface* can be converted into an in-memory *ModDetails*, described in Figure 5. (Technically, the *Module* does not have to be recorded as it is recorded in the *Name* associated with a *TyThing*; so you can think of a *ModDetails* as a big bag of type-checkable entities which GHC knows about; in the source code this is referred to as the *external package state (EPT)*).

$$\begin{aligned}
\text{ModDetails} &::= \langle \text{md_types}; \text{md_insts} \rangle \\
\text{md_types} &::= \text{TyThing}_0, \dots, \text{TyThing}_n \\
\text{md_insts} &::= \text{ClsInst}_0, \dots, \text{ClsInst}_n
\end{aligned}$$

Type-checked declarations

<i>TyThing</i>	Type-checked thing with a <i>Name</i>
<i>ClsInst</i>	Type-checked type class instance

Figure 5: Semantic objects in GHC

Type checking, thus, is a delicate balancing act between module interfaces and our semantic objects. Given a shaping, here are some important operations we have to do in type checking:

Imports When a module/signature imports a module name, we must consult the exports of *ModIfaces* associated with this module name, modulo what we calculated into the shaping pass. (In fact, we can get all of this information directly from the shaping pass.)

Includes and name lookups When we include a package, take all of the *ModIfaces* it brings into scope, type-check them with respect to the instantiation of holes and shaping, and add them to the EPT.

Even better, this process should be done lazily on name lookup. When we have a renamed identifier, e.g. a *Name*, we first check if we know about this object in EPT, and if not, we must find the *ModIface*(s) (plural!) that would have brought the object into scope, add them to EPT and try again.

Cross-package compilation When we begin type-checking a new indefinite package, we must *clear* all *ModDetails* which depend on holes. This is because shaping may cause the type-checked entities to refer to different semantic objects.

5.1 The basic plan

Given a module or signature of a package, we can type check given these two assumptions:

- We have a renamed syntax tree, whose identifiers have been resolved as according to the result of the shaping pass.
- For any **Name** in the renamed tree, the corresponding **ModDetails** for the **Module** has been loaded (or can be lazily loaded).

The result of type checking is a **ModDetails** which can then be converted into a **ModIface**, because we assumed each signature to serve as an uninstantiated hole (thus, the computed **ModDetails** is in its most general form). Arranging for these two assumptions to be true is the bulk of the complexity of type checking.

5.2 Loading modules from indefinite packages

Everything is done modulo a shape Consider this package:

```
package p where
  signature H(T) where
    data T = T
  module A(T) where
    data T = T
  signature H(T) where
    import A(T)

-- provides: A -> THIS:A { THIS:A.T }
--           H -> HOLE:H { THIS:A.T }
-- requires: H ->           { THIS:A.T }
```

With this shaping information, when we are type-checking the first signature for `H`, it is completely wrong to try to create a definition for `HOLE:H.T`, since we know that it refers to `THIS:A.T` via the requirements of the shape. This applies even if `H` is included from another package. Thus, when we are loading `ModDetails` into memory, it is always done *with respect to some shaping*. Whenever you reshape, you must clear the module environment.

Figuring out where to consult for shape information For this example, let's suppose we have already type-checked this package `p`:

```
package p (A) requires (S) where
  signature S where
    data S
    data T
  module A(A) where
    import S
    data A = A S T
```

giving us the following `ModIfaces`:

```
module HOLE:S.S where
  data S
  data T
module THIS:A where
  data A = A HOLE:S.S HOLE:S.T
-- where THIS = p(S -> HOLE:S)
```

Next, we'd like to type check a package which includes `p`:

```
package q (T, A, B) requires (H) where
  include p (A) requires (S as H)
  module T(T) where
    data T = T
  signature H(T) where
    import T(T)
  module B(B) where
    import A
    data B = B A
```

Prior to typechecking, we compute its shape:

```

provides: (elided)
requires: H -> { HOLE:H.S, THIS:T.T }
-- where THIS = q(H -> HOLE:H)

```

Our goal is to get the following type:

```

module THIS:T where
  data T = T
module THIS:B where
  data B = B p(S -> HOLE:H):A.A
  -- where data A = A HOLE:H.S THIS:T.T
-- where THIS = q(H -> HOLE:H)

```

This type information does *not* match the pre-existing type information from `p`: when we translate the `ModIface` for `A` in the context into a `ModDetails` from this typechecking, we need to substitute `Names` and `Modules` as specified by shaping. Specifically, when we load `p(S -> HOLE:H):A` to find out the type of `p(S -> HOLE:H):A.A`, we need to take `HOLE:S.S` to `HOLE:H.S` and `HOLE:S.T` to `THIS:T.T`. In both cases, we can determine the right translation by looking at how `S` is instantiated in the package key for `p` (it is instantiated with `HOLE:H`), and then consulting the shape in the requirements.

This process is done lazily, as we may not have typechecked the original `Name` in question when doing this. `hs-boot` considerations apply if things are loopy: we have to treat the type abstractly and re-typecheck it to the right type later.

5.3 Re-renaming

Theoretically, the cleanest way to do shaping and typechecking is to have shaping result in a fully renamed syntax tree, which we then typecheck: when done this way, we don't have to worry about logical contexts (i.e., what is in scope) because shaping will already have complained if things were not in scope.

However, for practical purposes, it's better if we don't try to keep around renamed syntax trees, because this could result in very large memory use; additionally, whenever a substitution occurs, we would have to substitute over all of the renamed syntax trees. Thus, while type-checking, we'll also re-compute what is in scope (i.e., just the `OccName` bits of `provided`). Nota bene: we still use the `Names` from the shape as the destinations of these `OccNames`! Note that we can't just use the final shape, because this may report more things in scope than we actually want. (It's also worth noting that if we could reduce the set of provided things in scope in a single package, just the `Shape` would not be enough.)

5.4 Merging ModDetails

After type-checking a signature, we may turn to add it to our module environment and discover there is already an entry for it! In that case, we simply merge it with the existing entry, erroring if there are incompatible entries.
